(Dated: February 10, 2010)

Calculations for infinite nuclear matter with realistic nucleon-nucleon interactions suggest that the isoscalar effective mass of a nucleon at the saturation density, m^*/m , equals 0.8 ± 0.1 . This result is at variance with empirical data on the level density in finite nuclei, which are consistent with $m^*/m \approx 1$. Ma and Wambach suggested that these two contradicting results may be reconciled within a single theoretical framework by assuming a radial-dependent effective mass, peaked at the nuclear surface. The aim of this exploratory work is to investigate this idea within the density functional theory by using a Skyrme-type local functional enriched with new terms, $\tau(\nabla\rho)^2$ and $\tau \frac{d\rho}{dr}$, where τ and ρ denote the kinetic and particle densities, respectively. We show that each of these terms can give rise to a surface peak in the effective mass, but of a limited height. We investigate the influence of the radial profile of the effective mass on the spin-orbit splittings and centroids. In particular, we demonstrate that the $\tau \frac{d\rho}{dr}$ term quenches the $1f_{5/2} - 1f_{7/2}$ splitting in ^{40}Ca , which is strongly overestimated within conventional Skyrme parametrizations.

I. INTRODUCTION

Irrespective of their level of sophistication, infinite nuclear matter (INM) calculations provide a relatively low isoscalar effective mass (IEM), $m^*/m \approx 0.8 \pm 0.1$, at the saturation density [1–5]. This finding is at variance with empirical data on the level density at the Fermi energy in finite nuclei, which are consistent with $m^*/m \approx 1$. Indeed, the level density close to the Fermi surface appears to be very well described within simple models using bare nucleonic mass and a phenomenological one-body potential, $U(\mathbf{r})$, of, e.g., the Woods-Saxon form [6–10].

It is not at all obvious, however, whether the success of such non-self-consistent approach is built upon solid theoretical foundations or is a mere effect of the fitting strategy of $U(\mathbf{r})$, which is adjusted precisely to the single-particle (SP) spectra. Indeed, rigorous and in principle exact treatment of the single-particle propagator (Green's function) is obtained within the Landau quasi-particle theory by solving the Dyson equation, which contains, in general, a spatially non-local and energy (frequency) dependent self-energy [11, 12]. Hence, from theory point of view, the use of static, momentum and energy (frequency) independent mean potentials seems to have no justification at all.

Quantitatively, the most important effect on the SP spectra is expected to come from spacial non-locality or momentum dependence of the mean potential. This effect is naturally taken into account in the Hartree-Fock (HF) approximation based on effective nucleon-nucleon (NN) interactions, like the most popular Skyrme [13] or Gogny [14] forces. Indeed, the zero-range Skyrme (pseudo-) potential depends explicitly on momentum. In case of the finite-range Gogny interaction, the effect enters through the exchange term. The energy dependence is considered only as a perturbation correction atop of

the HF result [15–19] and is usually completely ignored.

The self-consistent HF method involving the Skyrme or Gogny interactions leads to a non-uniform, position-dependent IEM, $m^*(\mathbf{r})/m$. Due to a rather restricted form of these forces, a typical IEM profile changes smoothly from the bare-mass value of 1 outside the nucleus to the INM value of 0.8 ± 0.1 in the nuclear interior. This lowers the nuclear level density at the Fermi surface usually well below the experimental value and, in turn, spoils the spectroscopic properties of these forces, see [20, 21] and references quoted therein.

The contradicting results concerning the SP level density in INM and finite nuclei are related to the fact that in finite nuclei the SP levels couple to low-lying collective surface vibrations, which leads to an increase of the IEM at the surface. Several authors argued that this effect can be taken into account within the random phase approximation, i.e., by going beyond mean field, see [17, 22, 23]. This viewpoint is difficult to reconcile with the density functional theory (DFT) that should warrant a proper radial dependence of the IEM through the fit to empirical data provided that the energy density functional (EDF), or the effective NN interaction, is rich enough to accommodate the anticipated increase of the IEM in the surface area.

Taking into account the particle-vibration coupling may help resolve the discussed controversy in the following way. The IEM is smaller than one inside the nucleus, as required for nuclear matter. On the other hand, it is peaked up at the surface, so that it may give one when averaged over the nuclear volume. This may allow to simultaneously reproduce the level density in finite nuclei.

The surface-peaked IEM was first explored by Ma and Wambach. In their seminal paper [24], they used a phe-

nomenological one-body Hamiltonian,

$$H(\mathbf{r}) = -\nabla \cdot \frac{\hbar^2}{2m^*(\mathbf{r})} \nabla + U(\mathbf{r}), \quad (1)$$

consisting of the Woods-Saxon potential with the spin-orbit (SO) term, $U(\mathbf{r})$, and the kinetic term with a radius-dependent IEM taken as follows,

$$\frac{m^*(\mathbf{r})}{m} = (1 - \alpha g(\mathbf{r})) \left(1 + \beta \frac{dg(\mathbf{r})}{dr} \right), \quad (2)$$

and depending on two adjustable constants, α and β , respectively. The function $g(\mathbf{r})$ is related to unperturbed self-energy,

$$g(\mathbf{r}) = \Sigma_0(\mathbf{r}, \mathbf{k}_F(\mathbf{r}), \epsilon_F) / \Sigma_0(0, \mathbf{k}_F(0), \epsilon_F). \quad (3)$$

It mimics the radial dependence of the SP potential and was chosen so that $\Sigma_0(\mathbf{r}, \mathbf{k}_F(\mathbf{r}), \epsilon_F) = U(\mathbf{r})$. It essentially follows the profile of the nucleonic density, $g(\mathbf{r}) \sim \rho(\mathbf{r})$. Ma and Wambach demonstrated that one can indeed unify the description of the SP levels in INM and finite nuclei by taking $m^*(\mathbf{r})/m \approx 0.7$ in the bulk and peaking it up at the nuclear surface to $m^*(\mathbf{r})/m \approx 1.2 \div 1.5$, depending on the nucleus. This result was later confirmed by Farine *et al.* [25] to hold in self-consistent HF calculations.

The aim of the present work is to explore the IEM modifications caused by the spacial non-locality of the NN interaction and by the particle-vibration coupling within a fully self-consistent model. Unlike Farine *et al.* [25], who obtained a surface-peaked IEM by adding new terms to the Skyrme interaction, we approach the problem from the perspective of the DFT, taking as a starting point the local Skyrme functional and adding new terms thereto. Nowadays, the nuclear EDFs are treated as basic entities, independent of the NN interaction. In this sense, our approach is more general and more flexible than the Skyrme HF theory.

In this exploratory work, we extend the Skyrme functional by adding two terms, which are described in detail in Sect. II. Their effect on the radial IEM profile is presented in Sect. III. In Sect. IV, we examine their influence on the SP levels. Sect. V contains a discussion of the results, particularly in connection with the recent studies of the tensor term. The paper is concluded in Sect. VI. All considerations presented in this work concern the isoscalar effective mass, and are limited to doubly-magic $N = Z$ nuclei. Such nuclei are spherical, which further simplifies the calculations.

II. EXTENDED LOCAL ENERGY DENSITY FUNCTIONAL

The local Skyrme EDF, $\mathcal{H}(\mathbf{r})$, consists of the kinetic and potential parts,

$$\mathcal{H}(\mathbf{r}) = \frac{\hbar^2}{2m} \tau_0 + \sum_{t=0,1} \mathcal{H}_t(\mathbf{r}). \quad (4)$$

For even-even nuclei,

$$\begin{aligned} \mathcal{H}_t = & C_t^\rho [\rho_0] \rho_t^2 + C_t^{\Delta\rho} \rho_t \Delta\rho_t + \\ & C_t^\tau \rho_t \tau_t + C_t^J \mathbb{J}_t^2 + C_t^{\nabla J} \rho_t \nabla \cdot \mathbf{J}_t. \end{aligned} \quad (5)$$

Index $t = 0, 1$ denotes isospin, and C_t are adjustable coupling constants. The constant $C_t^\rho [\rho_0]$ is density-dependent and equals $C_t^\rho [\rho_0] = C_t^{\rho'} + C_t^{\rho''} \left(\frac{\rho_0}{\rho_{0,eq}} \right)^\alpha$, where $\rho_{0,eq}$ is the INM saturation density. The potential energy terms are bilinear forms of time-even particle, kinetic, and tensor densities, ρ_t , τ_t , $\mathbb{J}_t$, and their derivatives. The density $\mathbf{J}_t$ is the vector part of the spin-current tensor, $\mathbf{J}_{t,\lambda} = \sum_{\mu\nu} \epsilon_{\lambda\mu\nu} \mathbb{J}_{t,\mu\nu}$. Since we consider $N = Z$ nuclei, only the isoscalar ($t = 0$) channel is active. Readers interested in details are referred, e.g., to Ref. [26].

Within this formalism, the IEM comes from variation of $\mathcal{H}$ over τ_0 ,

$$\frac{\hbar^2}{2m^*(\mathbf{r})} = \frac{\delta \mathcal{H}}{\delta \tau_0} = \frac{\hbar^2}{2m} + C_0^\tau \rho_0(\mathbf{r}). \quad (6)$$

Thus, $m^*(\mathbf{r})/m$ depends on the particle density. It is equal to one outside the nucleus and, for positive values of C_0^τ , smaller than one in the bulk. Therefore, the conventional Skyrme EDF contains only the volume term $\sim g(\mathbf{r})$ of parametrization (2).

In order to allow for a surface-peaked profile of the IEM one has to add new terms to the functional. Having an almost complete liberty in choosing their form, we decided to add either the term

$$\mathcal{H}_0^{(A)}(\mathbf{r}) = C_0^{\tau(\nabla\rho)^2} \tau_0(\mathbf{r}) (\nabla\rho_0(\mathbf{r}))^2 \quad (7)$$

or

$$\mathcal{H}_0^{(B)}(\mathbf{r}) = C_0^{\tau d\rho/dr} \tau_0(\mathbf{r}) \frac{d\rho_0(\mathbf{r})}{dr}. \quad (8)$$

We call these two variants of the model A and B, and explore them separately, never including both terms simultaneously.

The rationale behind these two choices is almost self-evident. Both terms are proportional to the kinetic density, τ_0 , and to derivatives of the particle density, ρ_0 . Hence, their variations give

$$\frac{\hbar^2}{2m^*(\mathbf{r})} = \frac{\hbar^2}{2m} + C_0^\tau \rho_0(\mathbf{r}) + C_0^{\tau(\nabla\rho)^2} (\nabla\rho_0(\mathbf{r}))^2 \quad (9)$$

and

$$\frac{\hbar^2}{2m^*(\mathbf{r})} = \frac{\hbar^2}{2m} + C_0^\tau \rho_0(\mathbf{r}) + C_0^{\tau d\rho/dr} \frac{d\rho_0(\mathbf{r})}{dr}, \quad (10)$$

for variants A and B, respectively. They modify the Skyrme value (6) at the nuclear surface, where the derivative of the particle density is large, and give small contributions elsewhere. Since the density gradient is negative in the surface region, while its square is positive, the peak is obtained for negative values of $C_0^{\tau(\nabla\rho)^2}$ in variant A, and for positive values of $C_0^{\tau d\rho/dr}$ in variant B.

The new terms also contribute to the mean potential according to the formula

$$U_0(\mathbf{r}) = \frac{\delta\mathcal{H}}{\delta\rho_0}. \quad (11)$$

This contribution is included self-consistently in our calculations.

The term A is a scalar, so its form is natural even if spherical symmetry is not assumed. The use of term B is restricted to nuclei of spherical shapes, what seems to be a disadvantage. We have decided to explore this term mainly because it mimics closely bulk and surface terms $\frac{m^*(\mathbf{r})}{m} \approx 1 - \alpha g(\mathbf{r}) + \beta \frac{dg(\mathbf{r})}{dr}$ of the Ma and Wambach parametrization (2).

The new terms introduced here are of completely different nature than those used by Farine *et al.* [25]. In their model, the IEM is modified not by the gradient of the density, but through its value,

$$\frac{\hbar^2}{2m^*(\mathbf{r})} = \frac{\hbar^2}{2m} + C_0^\tau \rho_0(\mathbf{r}) + C_0^\beta \rho_0^{\beta+1}(\mathbf{r}), \quad (12)$$

where β is a new parameter. In such an approach, the peak at the surface is not due to the slope of the density, but because the density there equals approximately half of its value in the interior.

In a preliminary study [27], we also investigated two other terms, τ^2 and $\tau\Delta\rho$. These, however, do not provide the expected radial profile of the IEM, and are not considered here.

III. RADIAL DEPENDENCE OF THE ISOSCALAR EFFECTIVE MASS

We base all our calculations on the SkXc Skyrme parametrization of Ref. [28]. This force was designed with particular attention to describe the SP levels, and has the IEM close to unity right from the beginning. We add our new terms to the SkXc functional, and vary some of its coupling constants as described below. We perform the calculations for three doubly-magic, $N = Z$, spherical nuclei, ^{40}Ca , ^{56}Ni , and ^{100}Sn .

As already explained, we aim at obtaining an IEM profile which provides $m^*(\mathbf{r})/m$ lower than one inside the nucleus and peaked at the surface, so that its mean value is close to one. In order to fulfill the latter condition we require that

$$\int d^3\mathbf{r} \frac{\rho_0(\mathbf{r})}{A} \frac{m^*(\mathbf{r})}{m} = 1, \quad (13)$$

where A is the mass number. A similar constraint was used by Ma and Wambach. Note that while the new coupling constants, $C_0^{\tau(\nabla\rho)^2}$ and $C_0^{\tau d\rho/dr}$, are responsible for the peak, C_0^τ accounts for lowering the IEM inside the nucleus. Thus, the condition (13) can be satisfied by an appropriate balance between the new coupling constants and C_0^τ .

TABLE I: Limiting values of the new coupling constants corresponding to the largest peak and anti-peak in ^{40}Ca .

	Largest anti-peak	Largest peak
$C_0^{\tau(\nabla\rho)^2}$	300 MeV fm ⁷	-280 MeV fm ⁷
$C_0^{\tau d\rho/dr}$	-30 MeV fm ⁶	70 MeV fm ⁶

FIG. 1: Isoscalar effective mass, $m^*(r)/m$, versus r in ^{40}Ca for variants A (left) and B (right). The solid (dashed) lines show the IEM profiles with the largest peak (anti-peak), obtained for the limiting values of the new coupling constants shown in Table I.

We proceed with the calculations for each of the considered nuclei separately in the following way. In both variants, we scan a range of the appropriate new coupling constant, and, for each value thereof, we readjust C_0^τ to fulfill the constraint (13), keeping all the remaining coupling constants frozen at their SkXc values.

For completeness, we examine both positive and negative values of each new coupling constant, which corresponds both to a peak and to an anti-peak at the surface. It turns out that the range of each new constant is limited in both directions. Beyond that range, rapid oscillations in the density occur, and the HF iterations diverge. The limiting values of the coupling constants give rise to the largest peak or anti-peak that could be obtained. As an example, we give those limiting values for ^{40}Ca in Table I, and show the corresponding IEM profiles in Fig. 1.

It can be seen from Fig. 1 that both variants of our model are rich enough to render a surface-peaked IEM. However, the height of the peak is rather limited. In variant A, the IEM in the nuclear interior is larger than ~ 0.9 and reaches only ~ 1.10 at the surface. These values equal ~ 0.8 and ~ 1.25 for variant B, respectively. For the same nucleus, Ma and Wambach quote the values of ~ 0.7 and ~ 1.25 . This result can be reproduced only in variant B of our model. It should also be mentioned that we failed to obtain a surface-peaked IEM with those Skyrme parametrizations which have a small effective mass in the INM limit, like $\sim 0.7 \div 0.8$.

IV. INFLUENCE OF THE ISOSCALAR EFFECTIVE MASS GEOMETRY ON SINGLE-PARTICLE LEVELS

We are now in a position to examine the influence of the new terms on SP spectra. Since our later discussion will mostly concern the SO properties, we consider the SO splittings,

$$E_{SO}(n, \ell) \equiv e(j = \ell - \frac{1}{2}, n, \ell) - e(j = \ell + \frac{1}{2}, n, \ell), \quad (14)$$

and the centroids of the SO partners,

$$E_C(n, \ell) \equiv \frac{1}{2} [e(j = \ell - \frac{1}{2}, n, \ell) + e(j = \ell + \frac{1}{2}, n, \ell)]. \quad (15)$$

Here, $e(j, n, \ell)$ are the SP energies. Since we are interested in delineating trends rather than details concerning the influence of the new terms on SP spectra we take $e(j, n, \ell)$ simply as eigen-energies of the one-body Hamiltonian, see discussion in Ref. [29]. To focus attention, we discuss only the neutron splittings and centroids.

Let us remind that within the DFT formalism, the SO splittings are determined by the SO field, $B_0(\mathbf{r})$, which is a derivative of $\mathcal{H}$ over $\mathbf{J}_0$, and, for spherical symmetry, equals

$$B_0(r) = C_0^J J_0 - C_0^{\nabla J} \frac{d\rho_0}{dr}, \quad (16)$$

where J_0 stands for radial component of the vector part of the spin-current $\mathbf{J}_0$. Since in most Skyrme parametrizations, including SkXc, the tensor coupling constant, $C_0^{\nabla J}$, is very small or zero, the SO field is in practice proportional to the gradient of the density, which is largest at the surface.

We perform two different types of calculations. In both cases we scan the whole admissible range of the new coupling constants, but:

- (i) For each value of the new coupling constant we readjust C_0^τ to fit the constraint (13), as in Sect. III. Hereafter, we call these calculations *perturbative*.
- (ii) In addition to adjusting C_0^τ to the condition (13), we attempt to refit also other coupling constants to masses and radii of the considered nuclei. These calculations will be dubbed *non-perturbative*, and are described in details below.

A. Perturbative calculations

The SO splittings and centroids obtained from the *perturbative* calculations in variant A are plotted in Fig. 2 in function of $C_0^{\tau(\nabla\rho)^2}$. Note that the peak appears for negative values of this coupling constant. As already discussed, the term A modifies the IEM profile rather weakly. Consequently, it also affects the SO splittings

FIG. 2: (Color online) Spin-orbit splittings (upper panels) and centroids (lower panels) in function of $C_0^{\tau(\nabla\rho)^2}$ obtained from variant A of the *perturbative* calculations in ⁴⁰Ca (left), ⁵⁶Ni (middle), and ¹⁰⁰Sn (right).

and centroids in a relatively modest way. Exceptions are the $1f_{5/2} - 1f_{7/2}$ splittings in ⁴⁰Ca and ⁵⁶Ni, and the $n = 2$ centroids, $2s$, $2p$, and $2d$.

In order to understand these results, let us inspect Fig. 3, which shows the particle density, ρ_0 , and its gradient in function of r for ⁴⁰Ca and ⁵⁶Ni, calculated in variant A for $C_0^{\tau(\nabla\rho)^2}$ equal to 0 and to the limiting value of -280 MeV fm^7 . It turns out that even the largest possible peak only weakly affects the density profile in the surface region, but quite strongly amplifies the density fluctuations inside the nucleus. Thus, the gradient of the density and the SO field are only moderately increased at the surface, which does not influence the SO splittings significantly. On the other hand, the modifications in the interior have more impact on low- ℓ states with wave functions inside the nucleus, than on higher- ℓ states, whose wave functions are more spread toward the surface.

The SO splittings and centroids obtained in variant B are presented in Fig. 4. Note that here the peak appears for positive values of $C_0^{\tau d\rho/dr}$. The tendencies are very different than in variant A. With the development of a surface-peaked IEM, one observes a systematic and substantial reduction of the SO splittings for high- ℓ orbits. In particular, the splittings for $n = 1$ orbitals, like $1d$, $1f$, $1g$, change by as much as 2 MeV throughout the entire range of $C_0^{\tau d\rho/dr}$. The splittings of the states with $n = 2$ and low- ℓ , including $2s$, $2p$, $2d$, are relatively weakly affected by the new term with no prevailing trend. However, these splittings are small, so their relative variations can still be as large as 20%. The centroids of all the calculated orbits go steadily up with $C_0^{\tau d\rho/dr}$. There

is also a tendency to increase the distance,

$$\Delta E = |E_C(n, \ell) - E_C(n+1, \ell-2)|, \quad (17)$$

between the SO centroids of, loosely speaking, the *pseudo-spin* partners.

The changes of the SO splittings and centroids with $C_0^{\tau dp/dr}$ can be nicely correlated with the changes in the radial dependence of the particle density shown in Fig. 5. With increasing $C_0^{\tau dp/dr}$, the density drops in the nuclear interior and the surface of the nucleus moves outward. Hence, also the gradient of the density and the SO field are repelled from the bulk, where the wave functions are located, and the SO splittings decrease. This argument is stronger for high- ℓ , $n=1$ orbits with an appreciable amount of the wave function in the surface region, and much weaker for low- ℓ , $n=2$ orbits, whose wave functions have one node inside the nucleus. The centroids move up in energy because the potential well becomes shallower and wider.

FIG. 3: Isoscalar particle density (upper panel) and its gradient (lower panel) versus radius obtained from variant A of the *perturbative* calculations in ^{40}Ca (solid lines) and ^{56}Ni (dashed lines) for $C^{\tau(\nabla\rho)^2} = 0$ (black lines) and for the highest-peak value of $C^{\tau(\nabla\rho)^2} = -280 \text{ MeV fm}^7$ (gray lines).

FIG. 4: (Color online) Spin-orbit splittings (upper panels) and centroids (lower panels) in function of $C^{\tau dp/dr}$ obtained from variant B of the *perturbative* calculations in ^{40}Ca (left), ^{56}Ni (middle) and ^{100}Sn (right).

B. Non-perturbative calculations

In the *perturbative* calculations, the new terms deteriorate the performance of the SkXc functional concerning the INM saturation energy, binding energy per nucleon, and the incompressibility modulus, as well as radii, binding energies, and SP levels in finite nuclei. The influence on the INM properties is illustrated in Fig. 6. This is so because the *perturbative* calculations take some coupling constants too far away from the SkXc values without readjusting the remaining ones. Hence, although helpful in understanding the response of the nucleus against the new terms, these calculations are of limited applicability. In this Section, we attempt to remove this drawback by refitting some other Skyrme coupling constants to selected radii, masses, and SP levels in finite nuclei.

We freeze the tensor and SO coupling constants, C_0^J and $C_0^{\nabla J}$, at their SkXc values. At each value of $C_0^{\tau(\nabla\rho)^2}$ or $C_0^{\tau dp/dr}$, the constant C_0^τ is adjusted to fulfill the condition (13), as in the *perturbative* calculations. Simultaneously, $C_0^{\rho'}$, $C_0^{\rho''}$, and $C_0^{\rho\Delta\rho}$, are refitted to minimize the merit function

$$\chi^2 = \sum_i \frac{(w_i^{(th)} - w_i^{(exp)})^2}{\sigma_i^2}. \quad (18)$$

Here, $w_i^{(th)}$ and $w_i^{(exp)}$ denote the theoretical and experimental values of the i -th observable, and the weight σ_i^2 is an *a priori* assumed error associated with the i -th observable. It may be understood as a desired theoretical accuracy. Observables used in the fit include masses and radii of ^{16}O , ^{40}Ca and ^{56}Ni , and the mass of ^{100}Sn . We

FIG. 5: Isoscalar particle density (upper panel) and its gradient (lower panel) versus radius obtained from variant B of the *perturbative* calculations in ^{40}Ca (solid lines) and ^{56}Ni (dashed lines) for $C^{\tau dp/dr} = 0$ (black lines) and for the highest-peak value of $C^{\tau dp/dr} = 70 \text{ MeV fm}^6$ (gray lines).

take σ_i^2 equal to 2 MeV for masses and 0.1 fm for radii.

It is not our intention to create a new functional here. We only aim at investigating the impact of the new terms on the SP levels while keeping the basic nuclear properties close to the SkXc values. This is why we fix the coupling constants C_0^J and $C_0^{\nabla J}$. Indeed, they influence the SO splittings and centroids directly through Eq. (16). By fixing them, we can track the response of the splittings and centroids solely to the new terms.

In the *non-perturbative* calculations, the masses of ^{40}Ca , ^{56}Ni and ^{100}Sn vary by less than $\pm 1\%$ throughout the whole range of the coupling constant $C_0^{\tau dp/dr}$ in variant B. The mass of ^{16}O varies within $\pm 5\%$. The INM properties are shown in Fig. 6. For most values of the new coupling constants, the saturation density stays within a range of $\pm 0.005 \text{ fm}^{-3}$ ($\pm 3\%$) with respect to the SkXc value, the binding energy per particle changes by no more than $\pm 0.6 \text{ MeV}$ ($\pm 4\%$) and the incompressibility modulus by less than $\pm 5 \text{ MeV}$ ($\pm 2\%$). These results guarantee that our refitted functional retains the basic characteristics of the SkXc parametrization and that new effects, if any, can be ascribed mostly to the new terms. The IEM profiles obtained from the *non-perturbative* calculations do not differ significantly from those given in Fig. 1.

The neutron SO splittings and centroids are shown in

FIG. 6: (Color online) Saturation density (top), binding energy per nucleon (middle), and incompressibility modulus (bottom) of infinite nuclear matter obtained from *perturbative* (green dashed lines) and *non-perturbative* (red solid lines) calculations in variant A (right) and B (left) in function of the corresponding new coupling constants.

FIG. 7: (Color online) Spin-orbit splittings (upper panels) and centroids (lower panels) in function of $C^{\tau(\nabla\rho)^2}$ obtained from variant A of the *non-perturbative* calculations in ^{40}Ca (left), ^{56}Ni (middle), and ^{100}Sn (right).

Figs. 7 and 8 for variants A and B, respectively. In variant A, there is almost no dependence of the splittings on $C_0^{\tau(\nabla\rho)^2}$, and only a small increase in ΔE in ^{56}Ni and ^{100}Sn occurring with the development of the peak. Variant B is more promising. Indeed, the previously observed trend of splittings decreasing with the onset of the peak is retained. The centroids move slightly up in energy and the values of ΔE are becoming systematically smaller.

Rigorous fits to bulk and SP data are necessary to corroborate or falsify our findings. However, this exploratory work demonstrates that construction of local functionals by adding specific, physically well motivated terms may constitute a promising alternative to the gradient-expansion method proposed recently in Ref. [33].
